ABSTRACT

A modular joint prosthesis includes a nail for insertion into a bone marrow canal, the nail having a nail neck. A neck piece has a proximal end, a middle shaft portion defining a longitudinal axis, and a distal end with a conical pin to which a slip-on joint ball can be attached. The proximal end of the neck piece has a helmet-shaped receiving head that includes an insertion opening for insertion of the nail neck or a module connector, a slot extending in the direction of the longitudinal axis, and corresponding recesses positioned on either side of the slot and extending perpendicularly to the longitudinal axis. The corresponding recesses receive a tensioning means which, in a tensioned state, clampingly fixes the nail neck or the module connector in the receiving head by frictional engagement in a jaw-like manner by application of tightening torque sufficient to prevent axial displacement and rotation.

MODULAR JOINT PROSTHESIS**CROSS-REFERENCE TO RELATED APPLICATIONS**

This application is a divisional of co-pending U.S. patent Ser. No. 13/120,628, filed Mar. 23, 2011, which application is incorporated herein by reference. U.S. patent application Ser. No. 13/120,628 is the U.S. national stage application of International Application No. PCT/DE2009/001272, filed Sep. 11, 2009, which International application was published on Apr. 1, 2010 as International Publication No. WO 2010/034284 A1 in the German language and which application is incorporated herein by reference. The International application claims priority of German Patent Application No. 10 2008 049 123.3, filed Sep. 26, 2008, which application is incorporated herein by reference.

The invention relates to a modular joint prosthesis having a curved head part, to the conical pin of which a slip-on joint ball is attached, and having a nail which can be inserted into the bone marrow canal of the long bone and has a nail neck, wherein between head part and nail neck a connecting means is provided which holds the head part in a non-rotatable manner.

The invention relates further to a modular joint prosthesis having a shaft-like shaped neck piece, to the conical pin of which a slip-on joint ball is attached, and having a nail which can be inserted into the bone marrow canal of the long bone and has a nail neck, wherein between neck piece and nail neck of the nail a connection means is provided which holds the neck piece in a non-rotatable manner in a predetermined angular position.

From DE 33 40 767 A1, an assembly set for a resection prosthesis having a head part and an end part is known, of which the one part has a conical pin and the other part has a conical bore, wherein between these two parts at least one intermediate part is provided which is adapted to pin and/or bore. The surfaces of the different parts abutting against each other when assembled can be secured against rotation by recesses which are adapted to each other.

This known prior art has the disadvantage that the prosthesis consists of a plurality of individual parts which requires a sustainable stock-keeping of these parts. In the assembled state, the individual parts must have the approximate shape of the curvature of the femur so that curvature and angular position which are suitable for the condition present in the respective patient can only be achieved through inventory holding of the adequate parts in order to restore the natural function of the joint to be replaced.

Furthermore, from EP 1 004 283 B1, an orthopedic prosthesis system for replacement of an articulating portion of a long bone is known which comprises a sleeve, a shaft, a neck and a connecting element. The connecting element has a connecting post which is formed with the shaft has a proximal end provided with a thread, and a nut positioned in the neck.

This known teaching might be modularly designed for differently long shafts and sleeves; however, the connecting element itself does not have such modularity.

The fundamental disadvantage of all these known prostheses is that their lengths and angular positions are not adjustable whereby the modularity is significantly limited.

Furthermore, said known prosthesis system has the disadvantage that during a later revision, significant problems can occur when detaching the connecting means which act exclusively in the axial direction because the axial connecting means can only be axially detached and removed which, in turn, can entail an undesired extension of soft, muscle and

tendon parts with associated traumatization. Also, apart from that, the tightening or loosening torque to be axially applied to the connecting means, in particular to the nail shafts, acts against a firm fit in the bone.

OBJECT OF THE INVENTION

In light of this prior art, the invention is based on the object to provide a modular joint prosthesis which increases the modularity of the prosthesis by increased length variability, allows an improved adjustability of the angular position while, at the same time, reducing the number of parts, and simplifies revision, surgeries.

This object is solved by a modular joint prosthesis of the aforementioned type with the features of claim 1 or claim 2.

Advantageous configurations of the joint prosthesis derive from the sub-claims.

The solution according to the invention is characterized in that a modular joint prosthesis with a wide variety of uses, for example for the proximal femur, in case of resections due to metastases in the bone, infections or trauma can be provided, which offers a high variety of variations with a small number of parts and an improved adjustability of the angular position.

The transmission of the maximum physiological loads, in particular forces and torques, into the long bone is achieved with particular advantage in that the connecting-means comprises at least one collar-like module which is arranged in the axial direction of the nail and has at least two half-shells which are divided in the axial direction of the module, are detachable connected to each other, form an axially extending passage with each other for inserting the nail neck into the passage, and have recesses which are arranged coaxially in the longitudinal direction of the module, are each positioned perpendicularly to the axis and correspond to each other, for receiving a tensioning means which, in the tensioned state, fixes the nail neck in the passage exclusively by means of frictional engagement in a jaw-like manner with a tightening torque sufficient to prevent axial displacement and rotation.

The transmission of the loads is also achieved in an advantageous manner by a neck piece of relatively short length which is formed at its distal end into a helmet-shaped receiving head which can be slipped onto the nail neck of the nail and has an insertion opening for inserting the nail neck or a connecting piece, wherein the receiving head is provided with a slot which runs in the direction of the longitudinal axis of the head part approximately as far as into the shaft and to which recesses are assigned which are each positioned perpendicularly to the axis and correspond to each other for receiving a tensioning means which, in the tensioned state, clampingly fixes the nail neck or the connecting piece in the receiving head of the head part exclusively by means of frictional engagement in a jaw-like manner with a tightening torque sufficient to prevent axial displacement and rotation. This ensures that a physiological force transmission into the femur can take place with optimal adaptation to the angular position of the conditions present in the patient.

The invention is based on the knowledge that a collar-like module which engages in a jaw-like manner on the nail shaft of the nail generates a frictional engagement between nail neck and passage which frictional engagement runs linearly along the circumference of the nail neck and reliably excludes an axial displacement and/or rotational movement of the parts involved in the connection, even in case of high loads. The linear contact excludes fretting at the contact points by the fact that reciprocating movements are prevented. The linearly acting frictional engagement is achieved by a profile provided

3

on the inner wall of the passage, wherein the neck diameter of the nail is adapted to the inner diameter of the passage.

With the tensioning means which are arranged directly next to each other in the longitudinal direction of the module, the frictional engagement can be secured by an adequately high tightening torque. A sufficiently high, tightening torque is generated by screwing hexagon socket screws with a torque wrench into the corresponding recess provided with an internal thread.

It is further of particular advantage that the jaw-like connection between the shaft of the nail on the one hand and the collar-like module or the receiving head on the other can be disengaged without any problems even during a revision and that the traumatization of the body tissue in the region of the joint can be kept very low. This is achieved in particular by the particularly advantageous ventral accessibility of the tensioning means at the collar-like module formed from half-shells as well as at the slotted receiving head, whereby the surgical intervention is significantly simplified.

Due to the length variability of the module for different lengths, the joint prosthesis according to the invention is well adaptable to the different anatomical conditions in the individual patients. Due to the fact that the receiving head, of the neck piece can be slipped onto the nail shaft of the nail and is retained in frictional engagement, it is also possible to continuously adjust the antetorsion angle and to keep the resection height to a minimum.

It is essential for the invention that the connecting means themselves are structured in a modular manner so that it is possible to take over the settings of an existing hip TEP and/or to combine components with different CCD angles.

Particular advantages are in particular achievable if modules of different or equal length are connected to each other by a module connector so that the length variability of the joint prosthesis according to the invention can be significantly increased.

The modular length variability of the joint prosthesis according to the invention can be increased according to an advantageous development of the invention by combining the module connector with the collar-like module so that the joint prosthesis can be assembled in different lengths in a modular manner. For connecting the module connector to the nail, in this case, in addition, a collar-like module is provided which has at least two half-shells which are divided in the axial direction of the module, are detachably connected to each other, form an axially extending passage with each other for inserting the nail neck into the one end and the module connector into the other end of the passage, and have recesses which are arranged coaxially in the longitudinal direction of the module, are each positioned perpendicularly to the axis and correspond to each other, for receiving a tensioning means which, in the tensioned state, clampingly fixes the nail neck in the passage exclusively by means of frictional engagement in a jaw-like manner with a tightening torque sufficient to prevent axial displacement and rotation.

In a further configuration of the invention, all parts of the joint prosthesis according to the invention have a rough surface to accelerate the ingrowth of the prosthesis in the surgically treated region.

In a further advantageous development of the invention, the outer diameter of the nail neck is adapted to the inner diameter of the passage in the connection module or the receiving head of the neck piece, wherein nails with different lengths and shaft lengths, but with the same diameter of the nail neck are provided.

4

All parts of the joint prosthesis according to the invention consist of a body-compatible and body-resistant, preferably metallic material, for example titanium, tantalum, niobium or their alloys.

Further advantages and details are apparent from the following description with reference to the attached drawings.

EXEMPLARY EMBODIMENTS

The invention is to be illustrated in more detail by means of two exemplary embodiments. In the figures:

FIG. 1 shows an exploded illustration of the joint prosthesis according to the invention with a bent, long head piece,

FIG. 2 shows a perspective view of a collar-like connection module for connecting nail shaft and head part,

FIGS. 3a to 3e show a top view of different connection modules of an assembly set with different lengths,

FIG. 4 shows a perspective view of a module connector,

FIG. 5 shows a perspective view of a stop or support module,

FIG. 6 shows an exploded illustration of a further variant of the joint prosthesis according to the invention having a short neck piece with receiving head,

FIGS. 7a to 7c show perspective views of the receiving head according to FIG. 6, and

FIGS. 8a to 8c show a view of the nails with different lengths.

EXAMPLE 1

FIG. 1 shows the basic structure of the joint prosthesis according to the invention in a first embodiment variant in an exploded illustration. The joint prosthesis according to the invention which is used, for example, in case of resections due to metastases in the bone, hip revisions or also in case of infections or trauma, is composed of a curved, one-piece head part 1 which is adapted according to the biomechanical conditions of the anatomy of the respective patient, a nail 2, for example femur nail, and a connection module 3. On the conical pin 4 of the head part 1, a slip-on joint ball 5 is arranged which engages with a non-illustrated joint socket. The distal end of the head part 1 is formed into a cylindrical shaft 6 from solid metal and is inserted into the connection module 3, which is described later, to be fastened therein.

The nail 2 is inserted into the bone marrow canal of the non-illustrated long bone and anchored therein. The nails 2 have different lengths and are anatomically adapted to the contour of the marrow canal in a suitable manner. They are sufficiently secured by locking screws or a star-shaped profile against rotation within the marrow canal.

The nail 2 has a cylindrical nail neck 7 made of solid metal. The shaft 6 of the head part 1 is rigidly connected to the nail 2 by means of the connection module 3 which encompasses the nail neck 7 and the shaft 6 in each case in a collar-like manner. The connection module 3—as shown in FIG. 2—is made of two pieces and consists of two cylindrical half-shells 8.1 and 8.2 which are formed in a substantially similar manner. Both half-shells 8.1 and 8.2 define in the assembled state a passage 9, the inner wall 10 of which has a profile 11 arranged perpendicularly to the longitudinal axis LA of the module. In each case four adjacent recesses 12.1 and 12.2 are incorporated in each of the half-shell walls 13 in such a manner that the recesses are arranged coaxially to the longitudinal axis LA of the module 3 and perpendicularly to the virtually extending dividing plane TE so that, for example, at least 8 recesses belong to the connection module 3. In the recesses 12.1 of the half-shell 8.2, an internal thread 14 is

5

incorporated into which a hexagon socket screw **15** can be screwed which is inserted through the recess **12.1** of the half-shell **8.1**.

The half-shells **8.1** and **8.2** together with the respective hexagon socket screw **15** and the internal thread **14** corresponding thereto form a jaw-like tensioning means **16** which, when tightening the hexagon socket screw **15**, abuts circumferentially against the cylindrical nail neck **7** and generates a plurality of circumferentially extending linear frictionally engaged connections between the profile **11** and the nail neck **7**. The outer diameter AD of the nail neck **7** is suitably adapted to the inner diameter ID of the passage **9**.

The resistance of said frictionally engaged connection against axial displacement or rotation of the components can be very accurately and exactly set by applying a defined tightening torque to the hexagon socket screw **15**. By allocating in each case four tensioning means **16** to the nail neck **7**, a secure connection between nail **2** and head part **1** is achieved.

All tensioning means **16** are aligned in a ventral direction and thus are accessible from the outside without any problems during a later revision, without the need to have to traumatize larger regions of the body's own tissue.

FIGS. **3a** to **3d** show different connection modules **3.1** to **3.4** with a lengths L, for example a connection module **3.1** with a length L1 (FIG. **3a**), a connection module **3.2** with a length L2 (FIG. **3b**), a connection module **3.3** with a length L3 (FIG. **3c**), and a connection module **3.4** with a length L4 (FIG. **3d**). It is to be understood that also the lengths of the connection modules can be selected according to the anatomical conditions of the respective patients.

FIG. **4** shows a module connector **17** which is shaped like a round bar and by means of which differently long or equally long connection modules **3.1** to **3.4** can be joined together. The module connector **17** consists of solid material, the diameter DM of which is adapted to the inner diameter ID of the passage **9**. The module connector **17** has a centrally arranged circumferential limit stop **18** with a diameter DA which is larger with respect to the inner diameter ID of the passage **9**. By inserting the respective ends of the module connector **17** into the respective end of the passage **9** of the connection modules **3.1** to **3.4** to be connected in each case and tensioning each of the associated tensioning means **16**, a frictionally engaged connection is generated between the module connector **17** and the connection modules.

Thereby it is possible to combine the individual connection modules **3.1** to **3.4** with each other and to achieve a high length variability.

The limit stop or support module **3.5** shown in the FIGS. **3e** and **5** serves as a height-adjustable support with respect to the long bone, for example femur.

EXAMPLE 2

FIG. **6** shows a further variant of the joint prosthesis according to the invention in an exploded illustration. This joint prosthesis comprises a shaft-like neck piece **19** of relatively short length and a nail **2**, for example femur nail. The essence of this variant of the invention is that the connection module **3**, which in example 1 is still a separate part, becomes an integral part of the shaft-like neck piece **19** so that a total of only two elements form the joint prosthesis according to the invention.

As in example 1, the neck piece **19** has a conical pin **4** onto which a slip-on joint ball **5** is arranged which engages with a non-illustrated joint socket. The distal end of the neck piece **19** is formed into a helmet-like receiving head **20** which has

6

an insertion opening **21** for inserting the nail neck **7**. The receiving head **20** is provided with a slot **23** which runs in the direction of the longitudinal axis LA of the head part **19** approximately as far as into the shaft **22** of the neck piece **19**. In the side walls **24**, in each case two recesses **25.1** and **25.2** are assigned to the slot **23** which recesses are positioned perpendicularly to the longitudinal axis LA and correspond to each other and serve for receiving a tensioning means **26** so that also the antetorsion angle can be continuously adjusted.

The inner wall **27** of the receiving head **20** is provided with a profile **28** arranged perpendicularly to the longitudinal axis LA of the neck piece **19** (see FIGS. **7a** and **7b**).

In the recesses **25.1** and **25.2** of the side walls **24**, an internal thread **29** is incorporated into which a hexagon socket screw **30** can be screwed which is inserted through the recess **25.1**.

The recesses **25.1** and **25.2** with their internal threads **28** together with the respective hexagon socket screw **30** and the slot **23** form the jaw-like tensioning means **26** which, when tightening the hexagon socket screw **30**, abuts circumferentially against the cylindrical nail neck **7** and generates a plurality of circumferentially extending linear frictionally engaged connections between the profile **28** and the nail neck **7**. The outer diameter AD of the nail neck **7** is suitably adapted, to the inner diameter ID of the insertion opening **21**.

The resistance of said frictionally engaged connection against axial displacement or rotation of the components can be very accurately and exactly set by applying a defined tightening torque to the hexagon socket screw **30**. By allocating in each case two tensioning means **26** to the nail neck **7**, a secure connection between nail **2** and neck piece **19** is achieved.

All tensioning means **26** are aligned in a ventral direction and thus are accessible from the outside without any problems during a later revision, without the need to have to traumatize larger regions of the body's own tissue.

Of course, it also belongs to the solution according to the invention if the module connector **17** illustrated in FIG. **4**, the outer diameter DA of which is adapted to the insertion opening **21**, is inserted into the insertion opening **21** of the receiving head **20** and an increased length variability of the joint prosthesis is achieved in that the nail neck **7** of the nail **2** and the module connector **17** are connected by differently long connection modules **3** (see FIGS. **3a-d**).

FIGS. **8a** to **c** show examples of nails of different length, the neck diameter AD of which is adapted to the inner diameter ID of the passage **9** of the respective connection modules **3.1** to **3.4** or the insertion opening **21** in the receiving head **20**.

All parts of the joint prosthesis according to the invention consist of a body-compatible and body-resistant metallic material. The outer surfaces are provided with a defined roughness, for example between 20 μm and 80 μm . This has the purpose, on the one hand, to increase the friction coefficient of the frictionally engaging partners and, on the other, to facilitate the ingrowth of the implant.

The configuration of invention is not limited to the aforementioned exemplary embodiments. Rather, variants are conceivable which can deviate from the illustrated solution also in case of fundamentally different configurations.

The invention claimed is:

1. A modular joint prosthesis comprising:

a nail for insertion into a bone marrow canal of a bone, the nail having a nail neck; and

a neck piece having a proximal end, a middle shaft portion defining a longitudinal axis, and a distal end comprising a conical pin to which a slip-on joint ball can be attached;

wherein the proximal end of the neck piece comprises a helmet-shaped receiving head, the receiving head comprising:

an insertion opening for insertion of one of the nail neck and a module connector;

a slot extending in the direction of the longitudinal axis; and

corresponding recesses positioned on either side of the slot and extending perpendicularly to the longitudinal axis;

wherein the corresponding recesses receive a tensioning means which, in a tensioned state, clampingly fixes the one of the nail neck and the module connector in the receiving head by frictional engagement in a jaw-like manner by application of a tightening torque sufficient to prevent axial displacement and a rotation,

wherein the module connector has a first end and a second end, and wherein the neck piece is indirectly coupled to the nail via the module connector.

2. The joint prosthesis of claim **1**, wherein the slot begins at the proximal end of the neck piece and ends before the middle shaft portion of the neck piece.

3. The joint prosthesis of claim **1**, wherein the middle shaft portion extends from the receiving head at an angle such that the middle shaft portion is not parallel to the nail.

4. The joint prosthesis of claim **1**, wherein one of an outer diameter of the nail neck and an outer diameter of the module connector corresponds to an inner diameter of the insertion opening.

5. The joint prosthesis of claim **4**, wherein the insertion opening comprises an inner wall having a profile extending transversely to the longitudinal axis for preventing micro-movements of the one of the nail neck and the module connector within the insertion opening.

6. The joint prosthesis of claim **1**, wherein the tensioning means comprises a hexagon socket screw that corresponds to an internal thread provided in the corresponding recesses.

7. The joint prosthesis of claim **1**, wherein the neck piece is directly coupled to the nail by insertion of the nail neck within the insertion opening.

8. The joint prosthesis of claim **1**, wherein all parts of the prosthesis comprise a biocompatible alloy.

9. The joint prosthesis of claim **8**, wherein the biocompatible alloy comprises a titanium alloy.

10. The joint prosthesis of claim **1**, wherein all parts of the prosthesis have a rough surface for facilitating growth of the bone thereon.

11. The joint prosthesis of claim **1**, further comprising a collar-like module for coupling the module connector to the nail neck, the collar-like module comprising, at least two half-shells which

are divided in an axial direction of the collar-like module, are detachably connected to each other,

form an axially extending passage with each other, a first end of the passage for insertion of the nail neck and a second end of the passage for insertion of the module connector, and

have corresponding recesses arranged coaxially along the axial direction of the collar-like module and extending perpendicularly to the axial direction, the corresponding recesses receiving a tensioning means which, in the tensioned state, clampingly fixes the nail neck in the first end of the passage and the module connector in the second end of the passage by means of frictional engagement in a jaw-like manner by application of a tightening torque sufficient to prevent axial displacement and rotation.

12. The joint prosthesis of claim **11**, wherein the first end of the module connector is inserted within the insertion opening of the receiving head and clamped therein, and wherein the second end of the module connector is inserted within the second end of the passage through the collar-like module and clamped therein.

13. The joint prosthesis of claim **12**, wherein an outer diameter of the module connector corresponds to an inner diameter of the insertion opening and to an inner diameter of the passage.

14. The joint prosthesis of claim **13**, wherein the passage comprises an inner wall having a profile extending transversely to the axial direction for preventing micro-movements of the nail neck and the module connector within the passage.

15. The joint prosthesis of claim **11**, wherein the collar-like module has a cylindrical shape when the at least two half-shells are connected to each other.

16. The joint prosthesis of claim **11**, wherein the collar-like module comprises first and second collar-like modules coupled to each other by insertion of a further module connector between the first and second collar-like modules.

17. The joint prosthesis of claim **16**, wherein, the first and second collar-like modules have different lengths.

18. The joint prosthesis of claim 17, wherein the first and second collar-like modules have the same diameter.

19. A modular joint prosthesis comprising:

a nail for insertion into a bone marrow canal of a bone, the nail having a nail neck; and

a neck piece having a proximal end, a middle shaft portion defining a longitudinal axis, and a distal end comprising a conical pin to which a slip-on joint ball can be attached;

wherein the proximal end of the neck piece comprises a helmet-shaped receiving head, the receiving head comprising:

an insertion opening for insertion of one of the nail neck and a module connector;

a slot extending in the direction of the longitudinal axis; and

corresponding recesses positioned on either side of the slot and extending perpendicularly to the longitudinal axis;

wherein the corresponding recesses receive a tensioning means which, in a tensioned state, clampingly fixes the one of the nail neck and the module connector in the receiving head by frictional engagement in a jaw-like manner by application of a tightening torque sufficient to prevent axial displacement and rotation, and

wherein the module connector has a centrally arranged circumferentially projecting limit stop defining a height-adjustable support.
